The Problem

Goal: the exhaustive test of the elementary functions for the TMD in a fixed precision (e.g., in binary64), i.e. "find all the breakpoint numbers x such that f(x) is very close to a breakpoint number".

Breakpoint number: machine number or midpoint number.

 \rightarrow Worst cases for f and the inverse function f^{-1} .

Vincent LEFÈVRE (INRIA / LIP. ENS-Lvon)

rarchical Approximations in LEMA

Hierarchical Approximations by Polynomials

Current implementation (but one could have more than 3 levels):

- Finding approximations must be very fast: from the previous one.
- Degree-1 polynomials: fast algorithm that computes a lower bound on the distance between a segment and \mathbb{Z}^2 (in fact, this distance, but on a larger domain) [filter] + slower algorithms when needed.

[hafp-in-lema.tex 35319 2010-02-26 08:06:23Z vinc17/prunille]

Computing the Successive Values of a Polynomial

Example: $P(X) = X^3$. Difference table:

On the left: coefficients of the polynomial in the basis

$$\left\{1, X, \frac{X(X-1)}{2}, \frac{X(X-1)(X-2)}{3!}, \ldots\right\}$$

Representation in the LEMA Tree

Computations can (and will) be done modulo some constant (much faster). \rightarrow The corresponding arithmetic must be supported by LEMA.

In practice, some coefficients will be close to 0 (either from above or from below). \rightarrow In the LEMA tree, notion of magnitude (like with real numbers).

How can this be expressed in LEMA?

- With a list (tuple) containing the coefficients? (But the degree *d* is not necessarily a constant parameter.)
- With a function taking two arguments *i* and *n* returning the coefficient a_i(n) of P(X + n) in the basis

$$\left\{1, X, \frac{X(X-1)}{2}, \frac{X(X-1)(X-2)}{3!}, \ldots\right\}?$$

The polynomial object is less visible, but this should be easier.

From an Interval to the Next One

The problem (to be considered recursively):

- Input: a polynomial P of degree d on an interval I.
- The interval I is split into subintervals J_n of the same length.
- The polynomial P will be approximated by polynomials P_n of degree d' on the intervals J_n (sequentially).
- Goal: generate code to compute the (initial) coefficients of P_n very quickly (from the work done for P_{n-1} on J_{n-1}).
- All errors need to be bounded formally: an acceptable error bound will be part of the input, and various parameters (the precision of the coefficients, etc.) will be determined from it.

From an Interval to the Next One [2]

Two methods:

• Take into account the computations that haven't been done, i.e. those involving the coefficients of degrees > d'.

 \rightarrow Linear combinations of coefficients: additions and multiplications of coefficients by integer constants (constant in the generated code).

Use the fact that the intervals J_n have the same length: each (initial) degree-i coefficient of P_n can be seen as the value of a polynomial a_i(n).
→ The difference table method can be used: only additions.

イロト イヨト イヨト

Error Bounds

Three kinds of errors:

- Error due to the approximation of function f by a polynomial.
- Approximation errors: coefficients of degree > d' are ignored.
 - \rightarrow Error bound of the form: $\sum_{i=d'+1}^{3} U_i \cdot |a_i(0)|$

where U_i depends on *i* and the size of the intervals *I* and J_n .

• Rounding errors on the coefficients a_i (due to their representation with an absolute precision n_i): initial errors and after each computation.

$$\rightarrow$$
 Error bound on $a_i(m)$ of the form: $\sum_{j=i}^{d^2-1} V_{i,j,m} \cdot 2^{-n_j}$.

Formally determining U_i and $V_{i,j,m}$ can be to difficult to be done automatically. But it should be possible to verify (prove) them with LEMA with conventional error analysis:

- with help of computer algebra software for generic formulas;
- numerically, after instantiation.

Distribution of the Jobs on Different CPU's

2 possibilities:

- Completely independent jobs (as with the current implementation): the domain is split into intervals *I*, on which *f* is approximated by a polynomial *P* and so on. If need be, the code generation can be done on a different machine.
- On some machine (regarded as a server), f is approximated by P on an interval I, which is split into N subintervals J_n ; the coefficients of P_n are computed directly. The corresponding N jobs are distributed on different machines.

Note: the input parameters can be chosen to control the size thus the estimated average execution time of a job (actually the order of magnitude).

LEMA Features That Will Be Needed

- Fast automatic generation of correct (in fact, proved) code, possibly with annotations (for provers, but this is currently limited because of the specific arithmetic).
- Possibility to test various parameters.
- Code instrumentation (was forgotten in most discussions), e.g. to count the number of word additions. For instance, transform the LEMA tree to replace a result x by a pair (x, c_x), and x + y by (x + y, c_x + c_y + 1)?
- Checking that the LEMA tree is correct, e.g. that formulas written by the human are correct.
